### ABSTRACT

**Background:** The Center for Disease Control (CDC) recently named childhood abuse histories as a public health risk. Clear links between abuse histories and inflammation exist. However, it remains unknown how abuse histories impact inflammatory trajectories throughout adulthood. Accordingly, this study assessed inflammatory trajectories across three visits among healthy adults with and without abuse histories.

**Method:** In this secondary analysis of data from a longitudinal observational study of cancer survivors and noncancer controls, 157 noncancer controls ( $M_{\text{age}} = 55.8$ , range = 32–83) completed the Childhood Experiences Questionnaire (CTQ), providing data on physical, emotional, and sexual abuse prior to age 18. Cytokines interleukin-6 (IL-6), interleukin 1-beta (IL-1 $\beta$ ), and tumor necrosis factor-alpha (TNF- $\alpha$ ) were collected at the baseline visit and two follow-up visits approximately one ( $M$  months = 11.52,  $SD = 4.10$ ) and two years ( $M$  months = 23.79,  $SD = 4.40$ ) later. To represent inflammatory changes, cytokine data at each visit were combined into a composite z-score. Covariates in all analyses included age, biological sex, race, income, body mass index, menopause status, psychological diagnosis history, and medical comorbidities.

**Results:** Compared to their nonabused peers, those who had experienced any type of abuse in childhood demonstrated steeper rises in inflammation across time. Inflammation rose more steeply for individuals with physical and emotional abuse histories compared to those without such histories.

**Conclusion:** Overall, these data suggest that childhood abuse histories may quicken age-related increases in inflammation, contributing to accelerated aging, morbidity, and early mortality. These findings provide mechanistic insight into why child abuse is a public health risk.

### 1. Introduction

Childhood trauma poses a significant threat to physical and psychological health because it occurs during a developmentally sensitive period. Trauma can dysregulate multiple stress-sensitive systems, including immune function. (Danese & McEwen, 2012). The Center for Disease Control (CDC) recently named child abuse as a serious public

health risk (CDC, 2019). Approximately one in seven children experiences child abuse each year, and the total lifetime economic burden of childhood abuse is approximately \$124 billion dollars per year (CDC, 2019).

The biological embedding hypothesis emphasizes that childhood adversity can lead to sustained physiological changes, thus putting an abuse survivor at an increased risk for poor health throughout adulthood

(Danese et al., 2011; Miller, Chen, & Parker, 2011). Childhood adversity is associated with many long-term health problems throughout adulthood, including cardiopulmonary symptoms, chronic pain, obesity, gastrointestinal issues, and lower self-rated health (Sachs-Ericsson, Blazer, Plant, & Arnow, 2005; Wegman & Stetler, 2009). In conjunction with the clearly identified risks to physical health, abuse histories predict depressive, anxiety, post-traumatic stress, and substance use disorders in adulthood (Green et al., 2010; McLaughlin et al., 2010; Scott et al., 2011).

Inflammation increases the risk for many chronic health problems and mortality (Miller et al., 2011). The association between inflammation and childhood abuse histories has been well-documented. For example, people who experienced childhood abuse had greater IL-6 reactivity to acute laboratory stressors compared to people who did not have such histories (Gouin, Glaser, Malarkey, Beversdorf, & Kiecolt-Glaser, 2012). Meta-analytic evidence suggests that adults who were abused as children have higher levels of C-reactive protein (CRP), interleukin-6 (IL-6), and tumor necrosis factor alpha (TNF-α) (Baumeister, Akhtar, Ciufolini, Pariante, & Mondelli, 2016; Tursich et al., 2014). Higher numbers of adverse childhood experiences, including abuse, were associated with increased CRP as well (Iob & Steptoe, 2019).

Despite evidence linking childhood abuse and inflammation, few longitudinal studies have addressed inflammatory trajectories among adults who experienced abuse. Among healthy older adults caring for family members with dementia, those who had experienced childhood abuse had higher IL-6 and TNF-α levels compared with those who were not abused (Kiecolt-Glaser et al., 2011). One longitudinal, prospective study found that adults who experienced abuse in childhood had higher CRP levels at 32 years old compared to those who did not. Childhood abuse histories predicted 10% of adult inflammation (Andrea Danese, Pariante, Caspi, Taylor, & Poulton, 2007). Examining how childhood adversity impacts inflammatory trajectories throughout adulthood will enhance our understanding of how abuse may accelerate aging, morbidity, and mortality (Franceschi et al., 2007).

The current study assessed inflammatory trajectories across three study visits among noncancer controls who participated in a larger longitudinal study. We hypothesized that physical, sexual, and emotional abuse histories would predict steeper increases in their inflammation across the three visits compared to those without such histories.

## 2. Method

### 2.1. Participants and procedure

Participants ( $N = 157$ ) were noncancer controls in a parent longitudinal observational study. Noncancer controls had an initial abnormal breast or colorectal cancer test followed by a benign diagnosis. Table 1 presents the baseline characteristics of the noncancer controls. The sample was 55.8 years old on average, 80% female, and predominately white (83%). The majority were married or in a domestic partnership (65%) and were employed full-time or part-time (60%).

At a baseline visit and at two follow-up visits approximately one ( $M$  months = 11.52,  $SD = 4.10$ ) and two years ( $M$  months = 23.79,  $SD = 4.40$ ) later, participants completed questionnaires and provided blood samples. The Ohio State University Institutional Review Board approved the project and all participants provided written informed consent.

### 2.2. Self-report measures

The Childhood Trauma Questionnaire (CTQ), a widely used 28-item self-report questionnaire, retrospectively assesses abuse and neglect experienced prior to age 18 (Bernstein et al., 1994). The CTQ includes questions related to physical (e.g., “people in my family hit me so hard that is left me with bruises or marks”), emotional (e.g., “people in my

family said hurtful or insulting things to me”), and sexual abuse (e.g., “someone tried to touch me in a sexual way or tried to make me touch them”). Participants responded on a 5-point Likert scale ranging from “never true” to “very often true” about childhood experiences. The CTQ demonstrates strong internal consistency and reliability across a range of samples worldwide (Viola et al., 2016).

The high-sensitivity cut-off scores for the CTQ were used to identify individuals reporting emotional (10 + ), physical (8 + ), or sexual abuse (8 + ) respectively (Walker et al., 1999). Additionally, individuals were classified as reporting any abuse if they scored above the threshold on one or more types of abuse. Dichotomous variables were used the four abuse categories (yes/no if someone experienced abuse). Participants completed the CTQ at their second visit.

### 2.3. Inflammation assays

Fasting blood samples were collected between 7:00 and 9:00 AM to

control for diurnal variation. Serum-derived tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin-6 (IL-6), and interleukin-1 $\beta$  (IL-1 $\beta$ ) were measured by using an electrochemiluminescence method with Meso Scale Discovery kits. Sensitivity was 0.3 pg/mL, 0.4 pg/mL, and 0.2 pg/mL for TNF- $\alpha$ , IL-6, and IL-1 $\beta$ , respectively. The intra-assay and inter-assay CVs for TNF- $\alpha$  were 4.32% and 5.30%, respectively; corresponding values were 1.43% and 4.42% for IL-6 and 4.15% and 4.03% for IL-1 $\beta$ . Each participant's frozen samples were assayed for all inflammatory markers at once, thus using the same controls for all time points for each person. Noncancer controls and cancer patient samples were mixed on the same plate.

#### 2.4. Covariates

All analyses controlled for physical comorbidities, menopause status (yes/no), body mass index (BMI), age, income, psychiatric disorder history, and biological sex. The widely used Charlson comorbidity index provided data on physical comorbidities (Charlson et al., 1994). The measure uses participants' self-reported health information to assign weights to 19 medical conditions (range, 1 to 37), with greater scores equal to greater comorbidity burden. Psychiatric disorder history was measured using the Structured Clinical Interview for DSM Disorders (SCID) (First et al., 2002).

#### 2.5. Statistical methods

**Analysis Sample.** The parent study enrolled a total of 198 control subjects. Abuse history was measured at the second visit, thus participants in the parent study who did not complete the second visit ( $n = 29$ ) were excluded from the analysis sample. An additional 11 participants were excluded who had incomplete cytokine data at all three study visits and thus could not have the z-score composite calculated. Finally, one subject did not have BMI data and was thus excluded. The remaining 157 did not significantly differ from the excluded subjects ( $n = 41$ ) in terms of age ( $p = .46$ ), BMI ( $p = .14$ ), number of comorbidities ( $p = .96$ ), or biological sex ( $p = .41$ ). One hundred and twenty participants provided cytokine data at Visit 1, 119 at Visit 2, and 67 at Visit 3. Additionally, there were not significant differences between included and excluded subjects on TNF- $\alpha$ , IL-6, or IL-1 $\beta$  at visit 1 ( $p > .20$  for all).

**Analysis Methods.** Linear mixed effects models were used to test for differences in the trajectories over time of cytokines between subjects who had abuse history and those who did not. Separate models were conducted for each abuse category (emotional, physical, sexual, and any abuse history). Importantly, these models allow participants with incomplete cytokine data at one or two visits to still be included. Fixed effects included visit (categorical), abuse history, and their interaction. Random effects included a subject-specific random intercept, accounting for within-subject correlation, as well as an assay-plate specific random intercept, accounting for the variability between assay plates. Age, BMI, physical comorbidities, and biological sex were adjusted for in all analyses. Serum cytokine values (TNF- $\alpha$ , IL-6, IL-1 $\beta$ ) were natural log transformed to better approximate normality of residuals and values more than three standard deviations above the mean were excluded from analysis. To capture overall inflammation, we also created a composite z-score combining the natural log transformed IL-6, TNF- $\alpha$ , and IL-1 $\beta$  variables. This method was previously used as a robust predictor of inflammation (Alfano et al., 2017; Liu et al., 2017). Specifically, each log-transformed cytokine was standardized using the visit 1 mean and standard deviation, and these three z-scores were summed for each subject to create the composite. The z-score composite had a mean of zero and standard deviation of 2.5 at baseline. Thus the increase across visits of + 1 units on the z-score composite represents 0.4 SD increase in inflammation. The Kenward-Roger adjustment to the degrees of freedom was used to control Type 1 error rates. A two-sided significance level of  $\alpha = 0.05$  was used for all tests. All analyses were carried out in SAS version 9.4 (SAS institute, Cary, NC).

### 3. Results

#### 3.1. Baseline rates of abuse

Twenty percent of the sample had a history of emotional abuse, 18% had a history of physical abuse, 15% had history of sexual abuse, and 32% of the sample had a history of any form of emotional, physical, or sexual abuse.

#### 3.2. Inflammatory change based on abuse history

Table 2 presents the means and standard deviations of the inflammatory composite at each visit. Table 3 presents correlations between all predictors, covariates, and the inflammatory composite variable. Fig. 1 shows the inflammatory trajectories by abuse history. Inflammation changed significantly over time for people who experienced emotional abuse ( $F(2,153) = 3.56, p = .03$ ), physical abuse ( $F(2,157) = 3.76, p = .03$ ), and any abuse ( $F(2,152) = 3.57, p = .03$ ), but not sexual abuse ( $F(2,151) = 1.41, p = .25$ ) compared to those without abuse histories. This pattern of results remained the same when controlling for depressive symptoms, measured by the Center for Epidemiological Studies Depression Scale (Radloff, 1977), rather than a history of a psychological disorder.

Individuals with an emotional abuse history had larger increases in inflammation (mean change from baseline = 0.97 and 1.84 at visits 2 and 3, respectively) compared to those without an emotional abuse history (mean change from baseline = 0.16 and 0.64 at visits 2 and 3). Similarly, individuals with a physical abuse history had larger increases in inflammation (mean change from baseline = 1.15 and 1.68 at visits 2 and 3) compared to those without physical abuse histories (mean change from baseline = 0.10 and 0.69 at visits 2 and 3). This pattern held when looking at any type of abuse; participants with any type of abuse history had larger increases in inflammation (mean change from baseline = 0.80 and 1.47 at visits 2 and 3) compared to those who did not report such a history (mean change from baseline = 0.09 and 0.58 at visits 2 and 3).

When analyzing the individual cytokines, only IL-6 showed significant differences in trajectories by physical abuse group ( $F(2,136) = 4.1, p = .02$ ). Trajectories of TNF- $\alpha$  did not significantly differ by any abuse type ( $p > .24$  for all). There were also no significant differences in trajectories of IL-1 $\beta$  by emotional and sexual abuse, though there were trends towards differences between subjects with physical abuse versus no physical abuse ( $F(2,155) = 2.86, p = .06$ ) and between subjects with any abuse versus no abuse ( $F(2,146) = 2.85, p = .06$ ).

#### 3.3. Alternative models

It is plausible that several factors may influence the relationship between abuse histories and inflammation. We therefore tested alternative models examining BMI and psychological disorder history as

**Table 2**  
Inflammation composite estimated means and standard errors across visits.

**Fig. 1.** Inflammatory trajectories based on different types of abuse histories.

moderators of how abuse influenced inflammation. There were no significant three way interactions among abuse, visit, and BMI (all  $p$ s > 0.18). Further, no significant three way interactions emerged among abuse, visit, and psychological disorder history (all  $p$ s > 0.07).

**4. Discussion**

Consistent with the biological embedding model, this study suggests that childhood abuse has lasting negative effects on inflammation throughout adulthood that worsens over time. Those who experienced any type of abuse during childhood (e.g., physical, emotional, or sexual abuse) had steeper increases in inflammation across the study visits compared to individuals without abuse histories. Participants who experienced emotional and physical abuse experienced steeper increases in inflammation across time compared to participants without abuse histories. In contrast, sexual abuse histories did not predict differential inflammatory trajectories across time in this study. Importantly, sexual abuse history rates were lower than physical or emotional abuse and thus the power to detect differences was much more limited.

This study contributes to a larger body of research examining abuse histories and inflammation in important ways. Other studies of middle-aged and older adults who experienced childhood abuse have reported higher inflammation at a single time point compared to those without

abuse histories (Gouin et al., 2012; Hostinar et al., 2015; Kiecolt-Glaser et al., 2011; Matthews et al., 2014; Slopen et al., 2015). However, research on inflammatory trajectories among people who experienced childhood adversity has been limited. Our study addressed this gap and showed how a history of childhood abuse can contribute to steeper increases in inflammation among middle-aged adults across an approximately two-year period. These findings are consistent with a previous longitudinal, prospective study that followed participants up to 32 years old and found that those who experienced childhood abuse had higher inflammation than those without such abuse (Danese et al., 2007). Our data extends prior literature by highlighting how inflammation increases across time for those who have abuse histories. These findings underscore the importance of examining the long-term biological implications of childhood adversity. These results align with the conserved transcriptional response to adversity, showing that early life adversity primes a heightened inflammatory response to stress in adulthood (Cole, 2019). Steeper inflammatory trajectories among those with abuse histories ultimately may result in accelerated inflammatory aging – or inflammaging – contributing to heightened risk for morbidity and mortality (Franceschi et al., 2007).

The current study has several notable strengths. Inflammation data across three time points allowed us to test trajectories of change based on histories of childhood abuse. Utilizing an inflammatory composite

variable demonstrated links between childhood abuse and inflammation across several inflammatory markers (Liu et al., 2017). This study showed that childhood abuse was linked to inflammation after adjusting for several important covariates including BMI, age, physical comorbidities, and biological sex. Limitations include the fact that the participants were not particularly diverse in terms of race and ethnicity. The CTQ uses retrospective reports of abuse. Prospective and retrospective abuse reports generally have low agreement with one another (Baldwin et al., 2019). Further, prospective reports of abuse previously correlated more strongly with objective markers of health (e.g., inflammation) compared to retrospective abuse reports (Reuben et al., 2016). Findings from the current study therefore should be replicated with prospective reports of abuse. Our findings did not demonstrate baseline differences in inflammation between those with abuse histories versus those without, potentially due to the biases inherent in these retrospective reports of abuse. One further possible explanation for these lack of baseline differences is that the participants in this study had recently had an abnormal breast or colorectal cancer test. Although these diagnoses were benign, these tests could have increased stress among our participants that ultimately influenced inflammation at baseline regardless of their history of abuse. The lack of significant baseline inflammatory differences between those with abuse histories compared to those without warrants further investigation. Additionally, only one aspect of early life stress was assessed in this study. Recent meta-analytic findings have shown a broad range of adverse early life experiences such as neglect, severe illness in childhood, and socioeconomic status can also influence inflammation both cross sectionally and longitudinally (Kuhlman, Horn, Chiang, & Bower, 2019).

Addressing the long-term health effects of childhood adversity is a clear priority of the Center for Disease Control (CDC, 2019). Childhood adversity's clear links to physical health issues in adulthood – including cardiovascular disease, diabetes, and cancer – highlight the necessity of identifying biological mechanisms underlying this relationship (Fagundes et al., 2013; Miller et al., 2011). This pattern of results suggests that inflammation may be one longitudinal mechanism linking childhood abuse to poor health in adulthood and underscores the need to address the persistent effects of childhood abuse history in these individuals.
